

11.6b — Hiding inherited functionality

BY ALEX ON JUNE 27TH, 2017 | LAST MODIFIED BY ALEX ON AUGUST 13TH, 2017

Changing an inherited member's access level

C++ gives us the ability to change an inherited member's access specifier in the derived class. This is done by using a *using declaration* to identify the (scoped) base class member that is having its access changed in the derived class, under the new access specifier.

For example, consider the following Base:

```
1  #include <iostream>
2
3  class Base
4  {
5  private:
6      int m_value;
7
8  public:
9      Base(int value)
10         : m_value(value)
11     {
12     }
13
14 protected:
15     void printValue() { std::cout << m_value; }
16 };
```

Because Base::printValue() has been declared as protected, it can only be called by Base or its derived classes. The public can not access it.

Let's define a Derived class that changes the access specifier of printValue() to public:

```
1  class Derived: public Base
2  {
3  public:
4      Derived(int value)
5          : Base(value)
6      {
7      }
8
9      // Base::printValue was inherited as protected, so the public has no access
10     // But we're changing it to public via a using declaration
11     using Base::printValue; // note: no parenthesis here
12 };
```

This means that this code will now work:

```
1  int main()
2  {
3      Derived derived(7);
4
5      // printValue is public in Derived, so this is okay
6      derived.printValue(); // prints 7
7      return 0;
8  }
```

Two notes:

First, you can only change the access specifiers of base members the derived class would normally be able to access. Therefore, you can never change the access specifier of a base member from private to protected or public, because derived classes do not have access to private members of the base class.

Second, as of C++11, using-declarations are the preferred way of changing access levels. However, you can also change access levels by using an “access declaration”. This works identically to the using declaration method, but omits the “using” keyword. This access declaration way of redefining access is now considered deprecated, but you will likely see older code using this pattern, so it's worth knowing about.

Hiding functionality

In C++, it is not possible to remove or restrict functionality from a base class other than by modifying the source code. However, in a derived class, it is possible to hide functionality that exists in the base class, so that it can not be accessed through the derived class. This can be done simply by changing the relevant access specifier.

For example, we can make a public member private:

```
1  #include <iostream>
2  class Base
3  {
4  public:
5      int m_value;
6  };
7
8  class Derived : public Base
9  {
10 private:
11     using Base::m_value;
12
13 public:
14     Derived(int value)
15         // We can't initialize m_value, since it's a Base member (Base must initialize it)
16     {
17         // But we can assign it a value
18         m_value = value;
19     }
20 };
21
22 int main()
23 {
24     Derived derived(7);
25
26     // The following won't work because m_value has been redefined as private
27     std::cout << derived.m_value;
28
29     return 0;
30 }
```

Note that this allowed us to take a poorly designed base class and encapsulate its data in our derived class. Alternatively, instead of inheriting Base's members publicly and making m_value private by overriding its access specifier, we could have inherited Base privately, which would have caused all of Base's member to be inherited privately in the first place.

You can also mark member functions as deleted in the derived class, which ensures they can't be called at all through a derived object:

```
1  #include <iostream>
2  class Base
3  {
4  private:
5      int m_value;
6
7  public:
8      Base(int value)
9          : m_value(value)
10     {
11     }
12
13     int getValue() { return m_value; }
14 };
15
```

```

16 class Derived : public Base
17 {
18 public:
19     Derived(int value)
20         : Base(value)
21     {
22     }
23
24
25     int getValue() = delete; // mark this function as inaccessible
26 };
27
28 int main()
29 {
30     Derived derived(7);
31
32     // The following won't work because getValue() has been deleted!
33     std::cout << derived.getValue();
34
35     return 0;
36 }

```

In the above example, we've marked the `getValue()` function as deleted. This means that the compiler will complain when we try to call the derived version of the function. Note that the Base version of `getValue()` is still accessible though.

Could you please confirm if I got the point correctly.

Previously you wrote that the object is comprised of portions, which means we have Base and Derived portions. So when we use `Base::m_value`; we basically create in Derived portion reference to a variable `m_value` from Base portion. We put reference into Derived portion private section, but in Base portion the variable `m_value` stays as it was in public domain.

Is it right?

Sorry for bad variables names.

Check:

```
1 #include <iostream>
```
